**d**  
dynamic rupture  
and slip

# MOTIVATION

**Figure 15.** A physical model of rupture nucleation. Hatched portion indicates the zone in which the breakdown (or slip-weakening) proceeds with time.

*Ohnaka 2003*

# MOTIVATION

EQ “damage” (strong ground motion + radiated waves) depends directly on the rupture velocity

## Radiation efficiency vs. Rupture speed

# MOTIVATION

Six **strike-slip** earthquakes have been documented up to now:

Imperial valley ( $M_w=6.5$  Ca. USA, 1979), Izmit ( $M_w=7.6$ , Turkey 1999), Duzce ( $M_w=7.2$  Turkey, 2000), Kulunshan ( $M_w=8.1$ , China, 2001), Denali ( $M_w=7.9$ , Alaska, USA, 2002), Indian Ocean ( $M_w=8.6$ , 2012)

Fig. 1. Comparison between the recorded ground motion (in black) for the Kullunshan earthquake and the one calculated (in red) for (A) a rupture velocity of 3 km/s and (B) the best-fitting rupture velocity, which averages 3.9 km/s. The component shown is the horizontal displacement in the direction transverse to the epicenter-station path; it starts with a reduced time equal to the epicentral distance divided by 4.5 km/s. The epicenter (star), the fault geometry (red line), and the station locations (triangles) are displayed.

*Bouchon et al, Science 2003*

1st segment : 2.8km/s

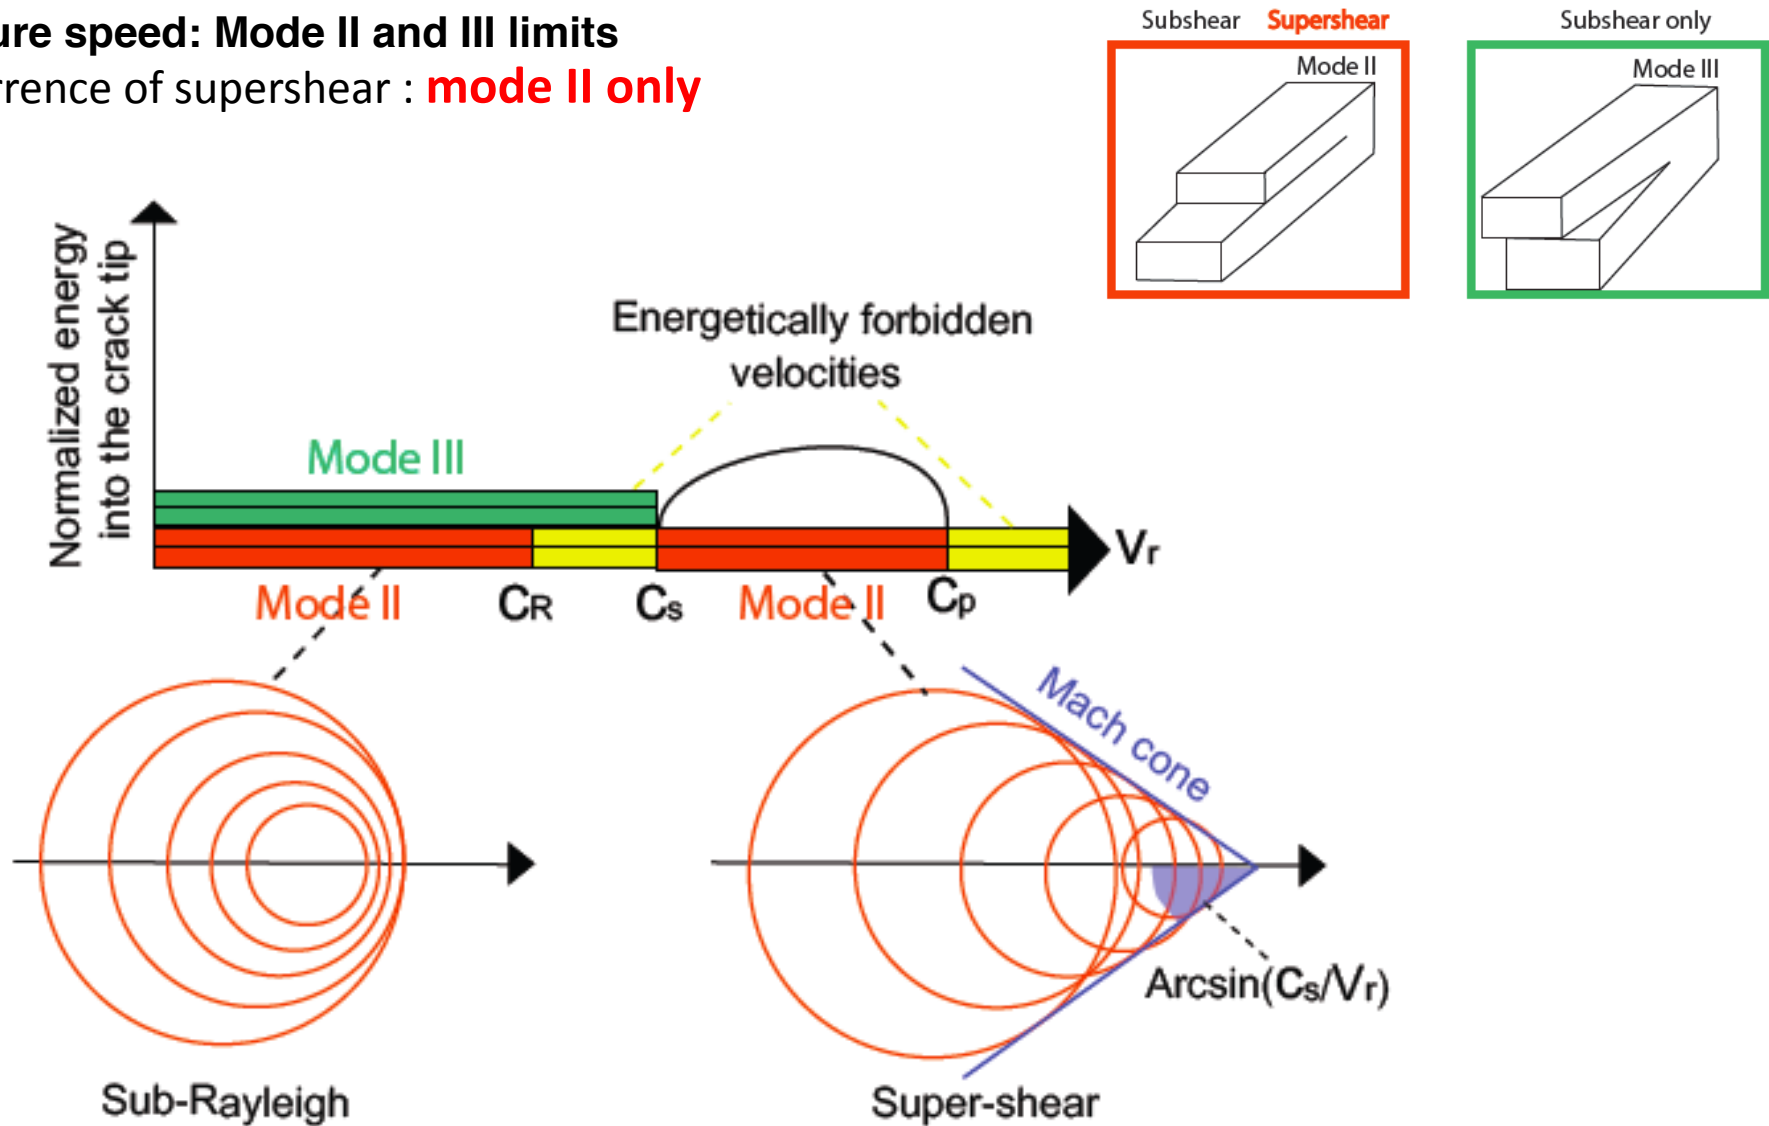

2nd and 3rd segment: 5km/s (supersonic for shear waves!)

4th segment: undetermined

# Reproducing depth in the lab

## (01) Triaxial apparatus - 100MPa/200°C

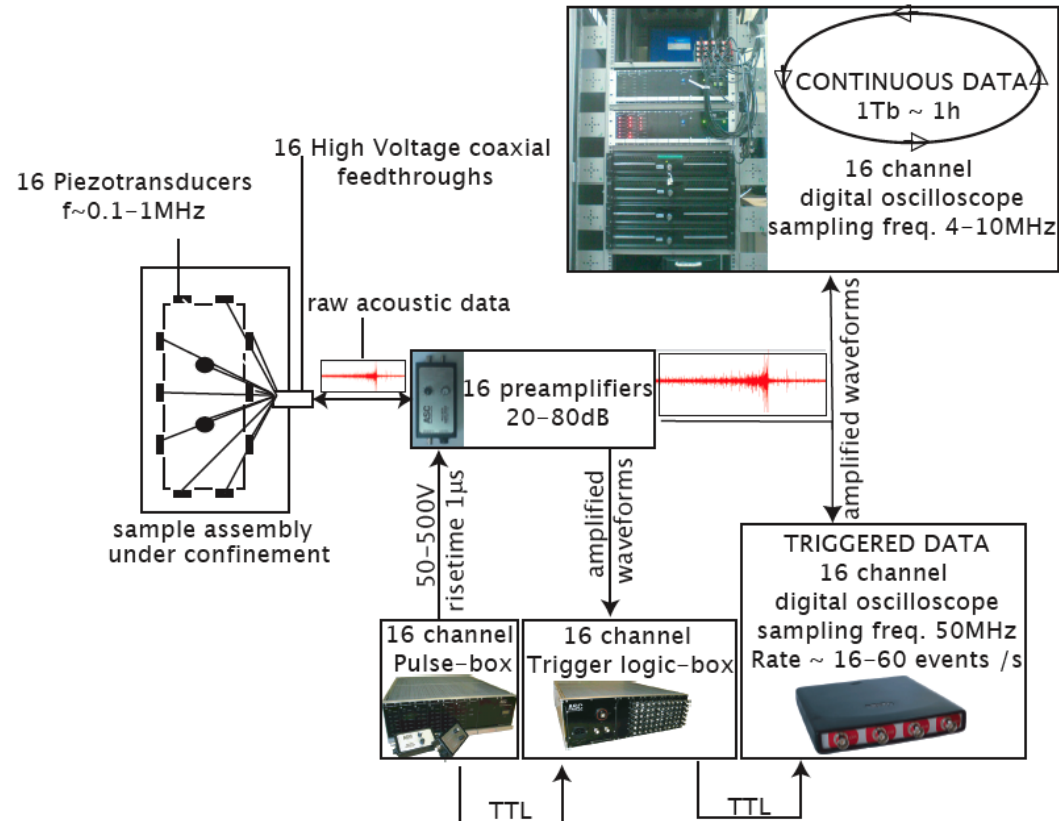

Scheme of the triaxial apparatus of the ENS

- Designed specially for acoustics
- Corrosive fluids injection (pH<3) in gas, water or supercritical phase
- Up to 100MPa confinement and pore pressure, 70 tons axial load

# Reproducing depth in the lab

## (02) Acoustic Recorder – 16 channels

- Continuous acoustic wfms recorded using Richter minisystem (ASC Ltd., 4 MHz sampling freq. on 16 channels)
- Triggered data - up to 16 events/ sec
- Each transducer can be used as source for velocity measures (P&S)

# Rupture speeds...

**INTACT SAMPLE of Fontainebleau sandstone**

Nucleation zone ( $\sim 1\text{cm}^3$ )

Quasi static to dynamic @  $> \text{mm/s}$

Terminal speeds  $\sim 10\text{m/s}$

a) Continuous acoustic waveforms vs. stress and strain

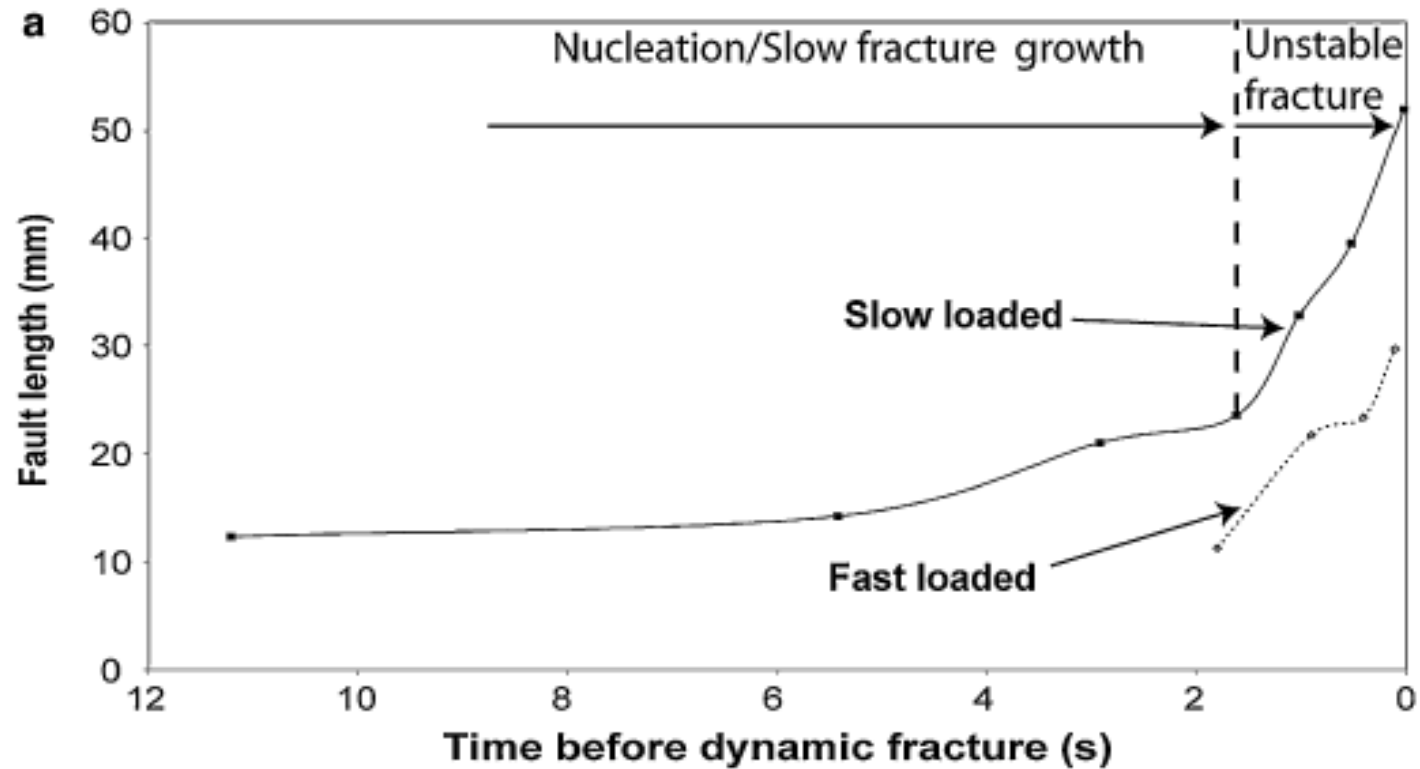

c) AE locations: fore-shocks and aftershocks

*Schubnel et al., 2007*

## 3. MECHANICAL DATA

# Measuring the rupture speed

$V_r$  estimated using arrival time of the rupture front passing by each sensor

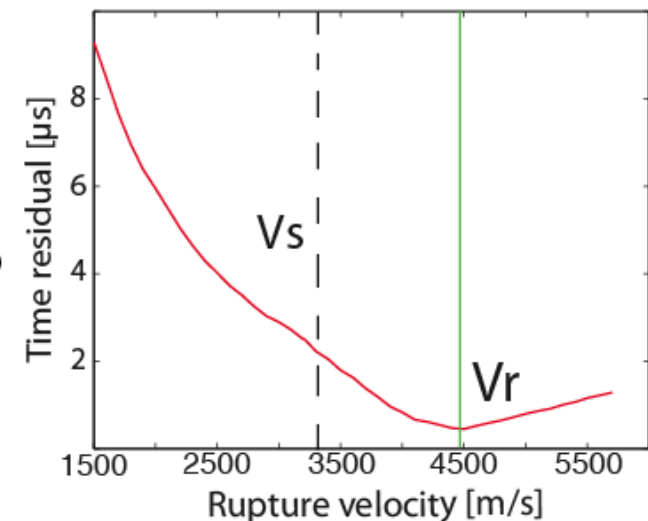

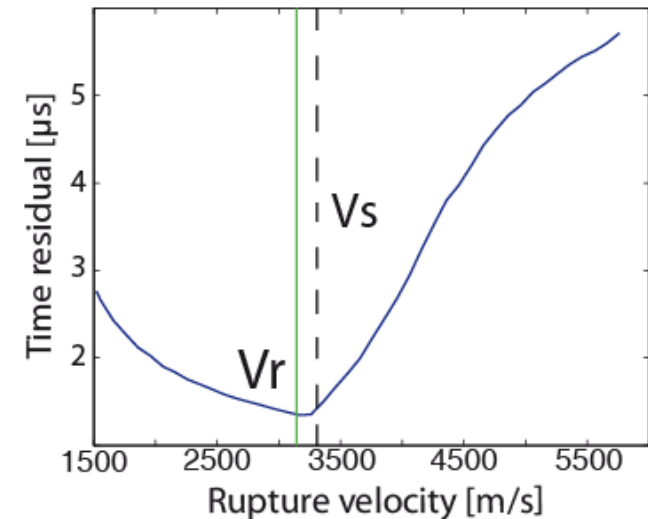

Calculation of the theoretical arrival time on each sensor for

- (i) nucleation point on the fault plane
- (ii) different initiation times
- (iii) different rupture front geometry

$$t^{th} = f(V_r, T_o, x, y)$$

Least square function between experimental and theoretical arrivals time

$$\min \left[ \frac{\sum (dt^d - dt^{th})^2}{N} \right] \Rightarrow (x, y, T_o, V_r)$$

# Sub-Rayleigh rupture during SSE

 slip pulse model  
 (Dunham and Archuleta, 2005)

# Transition length

Supershear rupture if the transitional length  $L$  is smaller than  $L_f$

Estimation using a semi-empirical law:

*Andrews, 1976*

*Xia et al., 2004*

$$L = \frac{39.2}{\pi(1 - \nu)} \frac{1}{(1.77 - S)^3} \frac{G\mu}{((f_s - f_d)\sigma_n)^2}$$

*Where  $S$  is the Seismic Ratio*

$$S = (\tau_p - \tau_0) / (\tau_0 - \tau_r)$$

*$G$  is the fracture energy*

*$\tau_0$  is the initial shear stress*

*$\tau_r$  is the residual shear strength*

*$\tau_p$  is the peak strength*

*$\nu=0.25$  Poisson ratio;  $\mu=24\text{GPa}$  shear modulus*

# Transition length

# Stress drops

# Frictional Heat: the mineral coupling

(for a crack-like rupture, 0.1 mm thickness)

Xrd of fault gouge particles

# CONCLUSIONS

- SS ruptures can be spontaneously reproduced on saw cut samples in rocks, because the transition length to SS, in upper crustal conditions, is a few cm only. So what slows down rupture? Geometrical effects, roughness, gouge, etc...?
- Nevertheless, SS ruptures observed for 2MPa stress drops only, indicates that asperities might punctually break in SS during EQ prop, while overall rupture SR. Importance consequence for EQ HF radiation.

**Figure 10.** (a) Stress drops of individual earthquakes within 5 km of the Hayward fault, shown projected onto the fault. Distance measured along the fault southeast of Pinole ( $37.9891^\circ$ ,  $-122.3546^\circ$ ), shown in Figure 1, assuming the fault strike is  $N35^\circ W$ . (b) Average stress drop in  $1 \times 1$  km bins on the Hayward fault surface, smoothed using a moving window of  $3 \times 3$  km. Averaging done in the log domain.

# CONCLUSIONS

Rupture nucleation:

- AEs correspond to microcracking (damage accumulation) - NOT TO RUPTURE
- AE rate prior and post rupture (ie number of Aes and AE rate) follows Omori's law but depend on the lithology and the porosity
- On intact samples, terminal rupture speeds  $<10\text{m/s}$ , so NOT FULLY DYNAMIC
- Nevertheless, we observe a variety of signals (LFAEs)

# CONCLUSIONS

Dynamic rupture propagation :

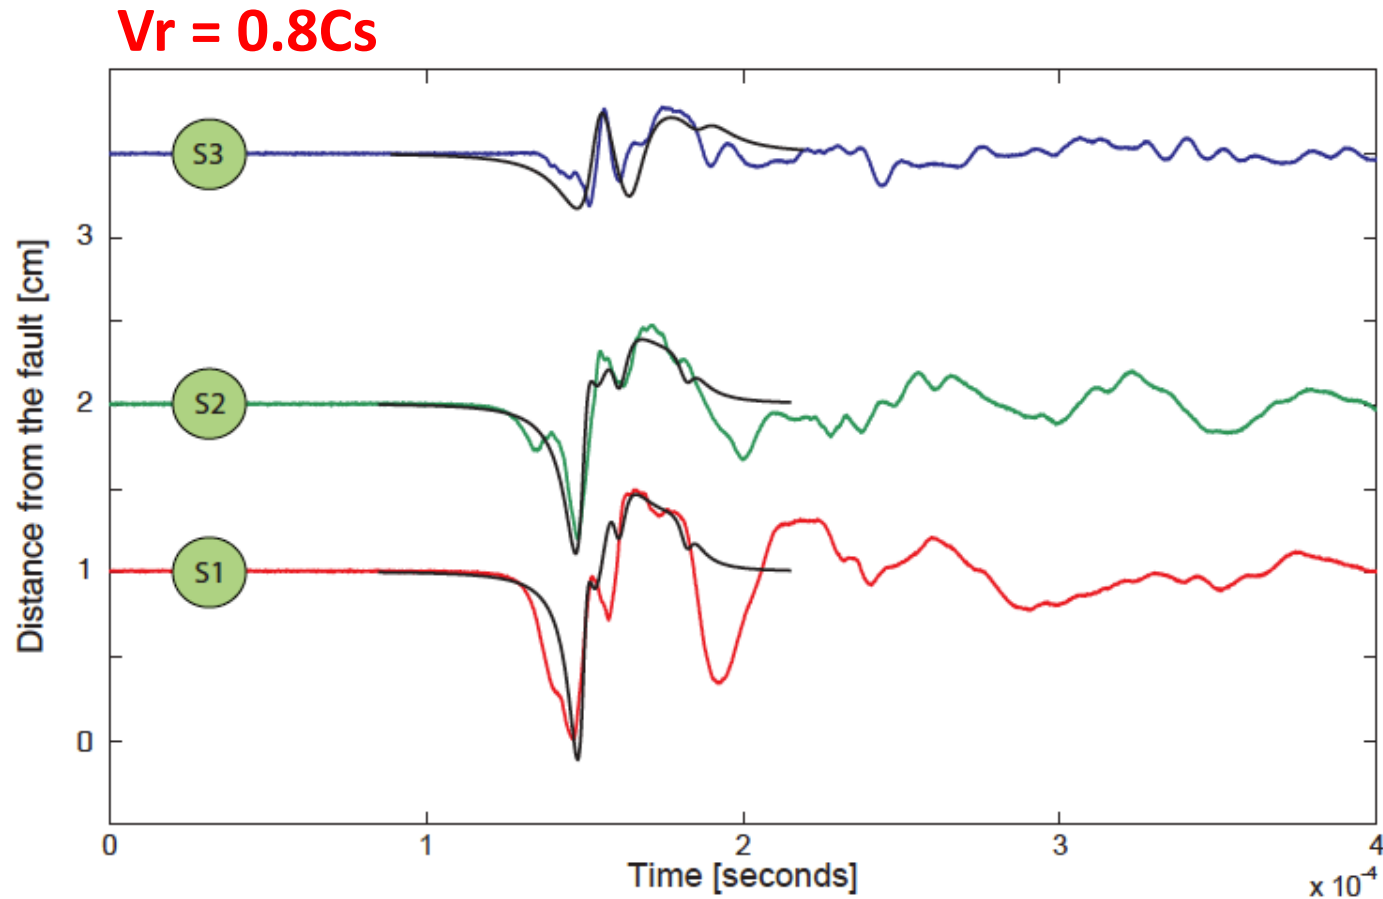

- SS and SR can be spontaneously reproduced on saw cut samples, both in resin and Rocks. SR happens at low prestress, SS at high pre-stress
- Rupture velocity can be determined using either images or acoustics independently
- Radiation due to dynamic rupture propagation is at least four or five orders of magnitudes larger than that produced by nucleation (or precursors)
- Introducing a kink, one introduces complexity (and HF)
- The experiment scales reasonably well with nature, except for slip.
- Even for a few tenths of mm slip, frictional heating term becomes predominant so that rupture becomes more dissipative and one can observe changes in the mineralogy
